Deep neural operators, such as DeepONets, have changed the paradigm in high-dimensional nonlinear regression from function regression to (differential) operator regression, paving the way for significant changes in computational engineering applications. Here, we investigate the use of DeepONets to infer flow fields around unseen airfoils with the aim of shape optimization, an important design problem in aerodynamics that typically taxes computational resources heavily. We present results which display little to no degradation in prediction accuracy, while reducing the online optimization cost by orders of magnitude. We consider NACA airfoils as a test case for our proposed approach, as their shape can be easily defined by the four-digit parametrization. We successfully optimize the constrained NACA four-digit problem with respect to maximizing the lift-to-drag ratio and validate all results by comparing them to a high-order CFD solver. We find that DeepONets have low generalization error, making them ideal for generating solutions of unseen shapes. Specifically, pressure, density, and velocity fields are accurately inferred at a fraction of a second, hence enabling the use of general objective functions beyond the maximization of the lift-to-drag ratio considered in the current work.

Nomenclature

\begin{align*}
m & = \text{Maximum camber in percentage of the chord} \\
p & = \text{Position of maximum camber in percentage of the chord} \\
t & = \text{Maximum thickness of the airfoil in percentage of the chord} \\
\rho & = \text{non-dimensional density} \\
u & = \text{non-dimensional velocity of the fluid in } x \text{ direction} \\
v & = \text{non-dimensional velocity of the fluid in } y \text{ direction}
\end{align*}
\( p \) = non-dimensional pressure
\( T \) = non-dimensional temperature
\( G \) = output of the DeepONet model
\( \theta_b \) = set of all trainable weights and biases of the branch network
\( \theta_t \) = set of all trainable weights and biases of the trunk network
\( N_\phi \) = number of basis functions learned by the DeepONet
\( \tau_{ij} \) = Components of viscous stress tensors
\( f \) = generalized input function to the DeepONet
\( \xi_g \) = Geometric parameter
\( c \) = Chord length
\( M a \) = Mach number
\( \xi_f \) = Flow parameter
\( Re \) = Reynolds number
\( Pr \) = Prandtl number
\( \alpha \) = output of the branch network
\( \phi \) = output of the trunk network
\( \tau_w \) = Wall Shear Stress
\( L \) = Lift
\( D \) = Drag
\( \vec{n} \) = Unit Normal
\( \vec{t} \) = Unit Tangent
1 Introduction

Neural networks that solve regression problems map input data to output data, whereas neural operators map functions to functions. This recent paradigm shift in perspective, starting with the original paper on the deep operator network or DeepONet [1, 2], provides a new modeling capability that is very useful in engineering – that is, the ability to replace very complex and computational resource-taxing multiphysics systems with neural operators that can provide functional outputs in real-time. Specifically, unlike other physics-informed neural networks (PINNs) [3] that require optimization during training and testing, a DeepONet does not require any optimization during inference, hence it can be used in real-time forecasting, including design, autonomy, control, etc. An architectural diagram of a DeepONet with the commonly used nomenclature for its components is shown in Figure 1. DeepONets can take a multi-fidelity or multi-modal input [4, 5, 6, 7, 8] in the branch network and can use an independent network as the trunk, a network that represents the output space, e.g. in space-time coordinates or in parametric space in a continuous fashion. In some sense, DeepONets can be used as surrogates in a similar fashion as reduced order models (ROMs) [9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19]. However, unlike ROMs, they are over-parametrized which leads to both generalizability and robustness to noise that is not possible with ROMs, see the recent work of [20].

![Figure 1: Schematic of a DeepONet.](image)

In the present work, we investigate the possibility of using DeepONets for representing functions over different solutions domains, something that has not been explored before. In particular, we focus on aerodynamic design by considering a classical problem of optimizing the shape of an airfoil at subsonic flow conditions. Aerodynamic shape optimization (ASO) of airfoils plays a vital role in the design of efficient modern commercial aircraft. The aerodynamic geometric optimization process is usually applied to the airfoil shape that forms the cross sections of the three-dimensional (3D) airfoil. The geometric optimization is performed to reduce the drag force while increasing the lift to enhance the aircraft’s fuel efficiency, hence reducing the transportation cost. The optimization process often requires a numerical model that predicts the flow field around a given airfoil geometry and computes the lift and drag for desired flow conditions. Traditionally, the numerical models are compressible flow numerical solvers, which are computationally intensive to accurately realize the flow field around a complex airfoil. Surrogate models can be introduced to circumvent the time-consuming part of the optimization loop where the numerical solver calculates aerodynamic forces.

ASO traditionally uses two main paradigms, gradient-based and gradient-free optimization approaches. The gradient-based approaches require the calculation of the cost function derivative with respect to the design variables. When the number of design variables exceeds a certain threshold, the gradient-based optimization becomes infeasible due to its expensive computational cost [21]. The adjoint formulation is derived from either the Euler or Navier-Stokes equations to make the gradient optimization independent of the design variables [22, 23, 24, 25]. Solving the adjoint equations can be as time-consuming as solving the governing equations (i.e., the rule-of-thumb is that forward and adjoint solutions together is at least twice the cost of the forward solver). Also, the optimization process can fall into
With the significant advancement in computational power, Deep Neural Network (DNN) tools have gained much attention for developing surrogate models. The DNN approach can be readily trained for numerous input design variables to predict the cost function of the optimization loop. The optimal airfoil design determined using the surrogate model was compared with an airfoil design obtained with a CFD-based optimization process. The surrogate model must reproduce a wide range of airfoil shapes and keep the number of design variables minimal. Various geometric parametric models have been employed for ASO. Carpentieri et al. [23] employed orthogonal Chebyshev polynomials to construct the airfoil curves. An orthogonal polynomial is used to cover the entire design space. Lepine et al. [32] used Non-Uniform Rational Basis Spline (NURBS) to parameterize a large class of airfoil shapes by only using 13 control points. Following the Lepine et al. [32] idea, Srinath and Mittal [25] also employed NURBS for the parameterization. Other researchers have used B-Spline [33] and Bezier [34] curves, Hicks and Henn’s functions [35] for airfoil shape construction. Painchaud-Ouellet et al. [36] used NURBS for the shape optimization of an airfoil within transonic regimes. They showed that using NURBS ensures the regularity of the airfoil shape. The airfoil shape can also be constructed using a deformation method [35]. This method adds a linear combination of bumps to a baseline airfoil shape for parameterization [37]. The Class function/shape function Transformation (CST) approach [39] employs Bernstein polynomials [40] to parameterize airfoils and other aerodynamic geometries. Other researches employed proper orthogonal decomposition (POD) [39] to reduce the number of design variables. In the current study, we employ the NACA 4-digits airfoil and NURBS parameterizations for the airfoil shape construction.

With the significant advancement in computational power, Deep Neural Network (DNN) tools have gained much attention for developing surrogate models [41][42][43]. The DNN approach can be readily trained for numerous input design variables to predict the cost function of the optimization loop. Du et al. [44] trained a feed-forward DNN to receive airfoil shapes and predict drag and lift coefficients. They also used RNN models for estimating the pressure coefficient. The optimal airfoil design determined using the surrogate model was compared with an airfoil design obtained with a CFD-based optimization process [44]. Liao et al. [45] designed a surrogate model using a multi-fidelity Convolutional Neural Network (CNN) with transfer learning. This learning method transfers the information learned in a specific domain to a similar field. The low-fidelity samples are taken as the source, and the high-fidelity ones are assigned as targets. Tao and Sun [46] introduced a Deep Belief Network (DBN) to be trained with low-fidelity data. The trained DBN was later combined with high-fidelity data using regression to create a surrogate model for shape optimization. Existing surrogate models for shape optimization are all trained to predict lift, drag, or pressure coefficients. In contrast, the flow field around the aerodynamic shape is not inferred. Here, we construct a surrogate model that predicts the flow field around the airfoil shape using a DeepONet. Predicting the flow field provides additional information that can be used in the cost function of the optimization loop. We aim to develop an aerodynamic shape optimization framework using a surrogate model that can infer the flow field around the geometry. The surrogate model is constructed using a DeepONet and is trained using high-fidelity CFD simulations of airfoils in a subsonic flow regime. The surrogate model is then implemented in two different optimization frameworks for shape optimization.

The parameterization of the geometry drastically affects ASO’s computational cost and accuracy. Parameterizing the geometry reduces the number of design variables through which the optimization algorithm must search. Reducing the number of design variables simplifies the optimization process and decreases the sensitivity to noise. The parametric model must reproduce a wide range of airfoil shapes and keep the number of design variables minimal. Various geometric parametric models have been employed for ASO. Carpentieri et al. [23] employed orthogonal Chebyshev polynomials to construct the airfoil curves. An orthogonal polynomial is used to cover the entire design space. Lepine et al. [32] used Non-Uniform Rational Basis Spline (NURBS) to parameterize a large class of airfoil shapes by only using 13 control points. Following the Lepine et al. [32] idea, Srinath and Mittal [25] also employed NURBS for the parameterization. Other researchers have used B-Spline [33] and Bezier [34] curves, Hicks and Henn’s functions [35] for airfoil shape construction. Painchaud-Ouellet et al. [36] used NURBS for the shape optimization of an airfoil within transonic regimes. They showed that using NURBS ensures the regularity of the airfoil shape. The airfoil shape can also be constructed using a deformation method [35]. This method adds a linear combination of bumps to a baseline airfoil shape for parameterization [37]. The Class function/shape function Transformation (CST) approach [39] employs Bernstein polynomials [40] to parameterize airfoils and other aerodynamic geometries. Other researches employed proper orthogonal decomposition (POD) [39] to reduce the number of design variables. In the current study, we employ the NACA 4-digits airfoil and NURBS parameterizations for the airfoil shape construction.

The novelties of this study include the following:

- Generating a DeepONet-based surrogate model, which is an efficient and inexpensive instantiation of the exorbitant CFD solver.
- The construction of the surrogate model is invariant to input space, which can be defined as low or high-dimensional parameterizations.
- Prediction of high-dimensional flow field can be used for various cost functions in the optimization loop.
- Drag and lift coefficients are computed using the inferred high-dimensional flow field, resulting in more accurate predictions.
- Integration of the Dakota optimization framework with the DeepOnet surrogate.
The rest of the article is organized as follows. We begin by defining the optimization process. We then present the data generation for training the surrogate model using the open-source spectral/hp element Nektar++ CFD solver. The training procedure of the DeepONet-based surrogate model is explained. Later, the optimization results using two different methods are represented. Finally, we summarize our findings in the Conclusions section. In the Appendix, we provide verification on the accuracy of the data generated by repeating selected simulations using different codes. Additionally, we provide validation of the Dakota optimizer by comparing against multiple approaches, and find that all the approaches studied converge to the same solution.

2 Problem setup

To highlight the capabilities of DeepONets as function-to-function maps that can be used within the airfoil shape optimization process, we start by reviewing the traditional end-to-end shape optimization pipeline augmented with DeepONet training. A schematic of the pipeline is shown in Figure 2. Reviewing the figure from upper left to lower right, we start with an experimental setup. This represents the determination of the feasible set from which the parametric airfoils in training will be drawn, the aerodynamic conditions, and any other engineering constraints related to the problem. We choose NACA four-digit airfoils as our geometric representation, which provides the upper and lower surface equations, given a random draw of parameters. This representation is then used in three places: (1) to directly mesh the flowfield around the airfoil for which we use Gmsh; (2) to use in querying the surrogate model on the surface of the airfoil when predicting the objective lift-to-drag ratio; and (3) as the branch input to the DeepONet function-to-function map, which is pre-processed using NURBS to lower the dimensionality.

In terms of creating the surrogate model, this can be viewed as the following forward problem. One deciphers the geometric and flow parameters, which are then used to create the inputs to a CFD solver: a geometric representation of the airfoil and its corresponding mesh to be used for approximating the flowfield and a flow parameter file. These are then input to a flow solver – in our case, the CFD solver Nektar++. Results from this solver are used to generate training data used to train our DeepONet surrogate. Finally, the lower-right quadrant of the diagram denotes the shape optimization process using the trained DeepONet surrogate. This process is recursive as the optimizer, for which we use Dakota, queries the DeepOnet surrogate model with new design parameters until the objective function is sufficiently minimized. This process differs from existing approaches because the bulk of the optimization process is done offline. Generating data using the CFD solver can be expensive, but with the final trained DeepOnet, the online cost of geometric optimization is orders of magnitude faster than other methods. Furthermore, as long as the objective can be created by the DeepONet flowfields trained over, a different objective function can be defined, not only lift-to-drag, and an airfoil can be quickly optimized with respect to the new objective without any additional cost.

For the purposes of our experiments, we have focused on using 2D compressible Navier-Stokes fields at Reynolds number $Re = 500$ and Mach number $Ma = 0.5$ for our training. These values have been chosen to allow us to focus on DeepONet’s ability to capture variations in domains (instead of the compounding effects of unsteadiness, etc.). Given the success of DeepONets under this experimental setup, future work will extend this pipeline to more complex flows and experimental conditions, such as varying the angle of attack, morphing geometry, handling unsteady flow, or going into the high speed flow regimes.

3 Methodology

3.1 Data Generation

For each example in the dataset, we define a set of geometric parameters $(\xi_g)$ and flow parameters $(\xi_f)$. The geometric parameters are then converted into another representation, such as surface coordinates derived from the NACA airfoil equations; this transformation is given by $\Gamma(\xi_g)$. These points are then used to mesh the flowfield domain with Gmsh [47], which is then input into the flowfield simulation software Nektar++ [48, 49]. We obtain the solutions fields from Nektar++ through post-processing for density, x-velocity, y-velocity, and pressure. This is saved in two sets, one in a subdomain around the airfoil for training the DeepONet, and one at airfoil sensors on the surface for validation. We also save the Nektar++ lift and drag forces for validation of the discrete integration of the airfoil forces.

3.1.1 Geometry generation

NACA 4-digit airfoils provide an excellent testbed application for geometry optimization using DeepONets since they can represent a wide range of shapes from well-known and studied parameterized geometric equations. Our geometry optimization framework could be easily extended to any parameterized geometry, such as NACA 5-digits or beyond.
Figure 2: Diagram of airfoil geometry optimization with a DeepONet surrogate model. The blue ovals indicate the beginning and end states of the method. The main intermediate steps are highlighted in colored boxes, whereas the auxiliary steps are grey parallelograms.

Following [50], we define the parametric equations for the surface of an airfoil with a chord length of one, as follows:

\[
y_t = \frac{t}{0.2} \left( a_0 \sqrt{x} + a_1 x + a_2 x^2 + a_3 x^3 + a_4 x^4 \right)
\]

\[
y_c = \begin{cases} 
\frac{m}{p^2} (2px - x^2) & \text{if } x < p \\
\frac{m}{(1-p)^2} (1 - 2p + 2px - x^2) & \text{if } x > p
\end{cases}
\]

\[
\theta = \tan^{-1} \left( \frac{dy_c}{dx} \right)
\]

\[
x_u = x - y_t \sin(\theta), \quad y_u = y_c + y_t \cos(\theta)
\]

\[
x_l = x + y_t \sin(\theta), \quad y_l = y_c - y_t \cos(\theta)
\]

where \(a_0 = 0.2969, a_1 = -0.1260, a_2 = -0.3516, a_3 = 0.2843, a_4 = -0.0105\). We can therefore define our geometry as a point cloud with coordinate sets \((x_u, y_u, x_l, y_l)\) parameterized by \(\xi_g = (t, p, m)\). A series of \(x\) locations are found using cosine spacing with 100 points; this increases the geometric fidelity around the leading and trailing edge, increasing the accuracy of the mesh and flowfield simulation at these important locations. To simplify the problem and reduce the likelihood of flow separation or turbulence, we constrain \(\xi_g\). The maximum thickness \((t)\) is set to a constant 0.15, and the domain of the parametric space left by the position of maximum camber \((p)\) and maximum camber \((m)\) is \(p \times m \in [0.2, 0.5] \times [0.0, 0.09]\). Therefore, for one geometric example in either the train or test set, we draw a \(\xi_g\) tuple where the variable parameters are drawn from a uniform distribution within their domains. We perform this draw 50 times and obtain the surface coordinates from Equations 1-3, splitting it into 40 training and 10 testing examples as seen in Fig. 3. The test/train split is an essential aspect of deep learning; here, we choose a relatively sparse sampling highlighting the ability of DeepONets to generalize well to unseen parameters.

Next, to lower the input dimensionality into the DeepONet branch, we fit the airfoil surface with Non-Uniform Rational B-Splines (NURBS) with 30 control points using geomdl [51]. This reduces the input dimensionality from 200 \((x, y)\) pairs to only 30.

### 3.1.2 Mesh generation

The meshes are generated using Gmsh [47] for parametrized airfoils geometry with a minimum characteristic length of 0.01 at parametrized locations. The airfoil flowfields are meshed using the 200 surface points exactly from the NACA equations, not the NURBS fit, which contains some inaccuracy. A spline function is used to represent the 1D geometry of the boundaries of airfoils. To resolve the flow at leading and trailing edges, meshes are refined by using the splitting approach [52]. The NURBS low-dimensional representation is a step to reduce overparameterization in the DeepONet, which is unnecessary for generating high-fidelity training data. The mesh generation for all 50 airfoils is automated using Gmsh’s Python API integrated with the geometry generation in Python, so no manual operations are needed. Fig.
Figure 3: Train and test set geometries sampled over the $\xi_g$ domain. Note that the numbers correspond to NACA airfoils and duplicate numbers are due to rounding to the nearest integer for readability. The true NACA parameters are drawn from a uniform distribution and are, therefore, real-valued.

Figure 4: Discretization of an airfoil with bounding domain. $\Omega_S$ represents the entire domain over which the compressible Navier-Stokes equations are solved. $\Omega_T$ (inset image with red border) represents the domain for which a DeepONet is trained. Inset image with yellow boundary represents the subdomain ($\Omega_W$) showing the mesh refinement around the airfoil.

shows the mesh of the entire simulated domain $\Omega_S$, which is then input into Nektar++ along with the flow parameters to generate the DeepONet training data. As seen in the figure, only a subset of the solved steady-state domain $\Omega_T$ is used in training the DeepONet. This is because the DeepONet is a function-to-function map and does not strictly obey boundary conditions or is affected by phenomena such as reflections due to the boundaries. It is performing regression on the dataset, not solving the system of equations, and therefore can be taken as a smaller domain, even without freestream conditions. Since the objective is geometric optimization, this subdomain simplifies the DeepONet training problem and cost of training.

3.1.3 Flowfield simulation

We used a compressible flow solver implemented in Nektar++ to generate the flow field data. The Nektar++ (www.nektar.info) is an open-source software framework [48, 49] designed to support the development of high-performance, scalable solvers for partial differential equations using the spectral/hp element method. The 2D compress-
We train four different DeepONet models to learn the pressure \( (p) \), density \((\rho)\), and velocity \((u, v)\) fields for a given airfoil geometry \((\xi_g)\) from the training data. The trunk network learns a collection of basis \((\phi)\) as functions of spatial coordinates, and the branch network learns the corresponding coefficients \((\alpha)\) as a function of the airfoil geometry. The DeepONet output is defined as

\[
G^q(\xi_g)(x, y) = \sum_{i=1}^{N_q} \alpha_i(\xi_g; \theta^q_i) \phi_i(x, y; \theta^q_i) \quad q \in \{p, \rho, u, v\}.
\]

In the case of airfoils, the geometry can be fed into the branch network by directly providing the geometric parameter, \(\xi_g\). However, \(\xi_g\) need not exist explicitly for a general arbitrary geometry. Under such a scenario, the geometry

\[
\frac{\partial p}{\partial t} + \frac{\partial pu}{\partial x} + \frac{\partial pv}{\partial y} = 0
\]

\[
\frac{\partial pu}{\partial t} + \frac{\partial p u^2 + p}{\partial x} + \frac{\partial p uv}{\partial y} = \frac{1}{Re} \left( \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} \right)
\]

\[
\frac{\partial pv}{\partial t} + \frac{\partial p uv}{\partial x} + \frac{\partial p v^2 + p}{\partial y} = \frac{1}{Re} \left( \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} \right)
\]

\[
\frac{\partial E}{\partial t} + \frac{\partial (E + p) u}{\partial x} + \frac{\partial (E + p) v}{\partial y} = \frac{1}{Re} \left[ \frac{\partial \left( u \tau_{xx} + v \tau_{xy} + \kappa \frac{\partial T}{\partial x} \right)}{\partial x} + \frac{\partial \left( u \tau_{xy} + v \tau_{yy} + \kappa \frac{\partial T}{\partial y} \right)}{\partial y} \right]
\]

where \( p = R \rho T, R = \frac{1}{\gamma M_{\infty}^2}, \kappa = \frac{\gamma - 1}{\gamma} \frac{\mu_0}{\mu R}, \) with \( \mu \) being the non-dimensional viscosity and computed by using the Sutherland law as

\[
\frac{\mu}{\mu_0} = \left( \frac{T}{T_{\infty}} \right)^{3/2} \frac{1 + C/T_{\infty}}{T + C/T_{\infty}}.
\]

is often represented using the NURBS control points. To demonstrate the effectiveness of using a DeepONet in either of the situations, we investigate parameter-DeepONet that directly takes \( \xi \) as the branch network input and NURBS-DeepONet that takes NURBS control points of the airfoil geometry as the input to the branch network. The hyperparameters of the DeepONet used in this study are provided in Table 2.

3.2.3 Lift and Drag calculation

We present two ways to evaluate the objective function – in our case, lift-to-drag. The map created by the trained DeepONets takes an input geometry and spatial \((x, y)\) location in the output space and returns the value of the field at that location. So it follows that to estimate the lift and drag, we simply evaluate the discrete integral over the surface of the airfoil, for which the \((x, y)\) points are easily generated for objective function queries by Equations 1-3. The discrete integrals for lift and drag given by Equations 8 & 9 subject to the approximation of wall shear stress in Equation 7.

\[
\tau_w = \mu \frac{dU}{d\vec{n}} = \mu \frac{dU}{d\vec{n}} \quad (7)
\]

\[
L = \int dF_x = \sum \rho \vec{n}_x dS + \sum \tau_w \vec{t}_x dS \quad (8)
\]

\[
D = \int dF_y = \sum \rho \vec{n}_y dS + \sum \tau_w \vec{t}_y dS \quad (9)
\]

For the first term in the aerodynamics forces, the pressure is directly obtained from one of the DeepONet predictions. In the second term, the viscosity \( \mu(p, \rho) \) is obtained by Equation 5 as a function of the pressure and density DeepONets. Finally, the change in speed of the flow over the airfoil surface \( \frac{dU}{d\vec{n}} \), is obtained in two ways:

1. Finite-difference (A):

\[
\frac{dU}{d\vec{n}} = \frac{-U_2 + 4U_1 - 3U_0}{2h} \quad (10)
\]

2. Automatic-differentiation (B):

\[
\frac{dU}{d\vec{n}} = (v_y - u_x)\sin\theta\cos\theta - v_x\sin^2\theta + u_y\cos^2\theta
\]

where \( h = 0.001 \) and \( \theta \) is the angle between the x-y axis and each segment’s normal-tangential axis. Approach (A) is a second-order forward finite difference approximation obtained by sampling the x-velocity and y-velocity DeepONets at the appropriate locations defined by the surface normal and spacing \( h \). Approach (B) utilizes the now well-known development in automatic differentiation [50], primarily utilized in physics-informed machine learning for approximating partial derivatives to obtain the PDE residual. Here, since the DeepONet directly takes in the spatial \((x, y)\) coordinates and outputs the velocity components \((u, v)\), the computational graph is complete and the partials \((u_x, u_y, v_x, v_y)\) can be estimated with this method. The required sampling for each method is shown in Fig. [5] While (A) takes three times the amount of point evaluations, (B) requires the gradients to be computed, so the cost of each can be viewed as similar. However, the flexibility of using automatic differentiation in this way may allow for more complex objective functions in the future given the right mapping and subsequent computational graph.

4 Results

4.1 Results from DeepONet model

The training and testing relative \( L^2 \) error of the NURBS and parameter-based DeepONets for all four different fields are reported in table [5] We observe that the NURBS and parameter-based DeepONets predict fields with similar
Figure 5: Illustration of the discrete integral for lift and drag. The points in red indicate the surrogate model samples used in the construction of the approximation to \( \frac{dU}{dn} \) with a finite difference approximation of the gradient or the automatic differentiation approximation using the direct network gradients.

accuracy. NURBS-DeepONet has marginally better predictions on the pressure field, while parameter-DeepONet generates marginally better predictions for velocity and density fields. The main takeaway is that either representation is sufficient for the geometry optimization of this experiment. However, we must consider that in the future more complex geometries may be used, particularly in the sense of local morphing. Therefore, the NURBS representation will likely be necessary as a direct parameter mapping may miss local nuances. The predicted fields and the absolute pointwise error by the best DeepONet models for the flowfield parameters are shown in Fig. 6. It can be seen that the global prediction is, in general, accurate; the error is primarily localized to the airfoil’s leading edge. In the future, adaptive weighting schemes will be used to improve DeepONet training, particularly at the points of difficulty, such as the surface and leading edge. The corresponding relative \( L^2 \) error of the fields over the entire dataset is shown in Fig. 6. We observe minimal generalization error and that DeepONets are globally accurate.

Regarding geometry optimization, we must concern ourselves not only with the global flowfield accuracy, but also with the accuracy on the surface of the airfoil in particular. Fig. 8 shows the corresponding surface prediction plots for the same airfoil presented in Fig. 7 as a function of the x-direction over the airfoil. We observe good accuracy in the pressure and density fields, which will provide very accurate predictions of the lift and drag force components.

Figure 6: Error Scatter Plots. The relative \( L^2 \) error corresponding to each of the train and test samples for pressure, velocity, and density fields, with respect to the DeepONet predictions, are shown in this figure.
Figure 7: DeepONet Predictions. The pressure, density, and velocity fields around the test set airfoil NACA 7315 predicted by the DeepONet, and the corresponding pointwise absolute errors are also provided.
due to pressure as well as the viscosity $\mu(p, \rho)$, which is a function of these fields per Equation[5]. The surface’s $x$ and $y$ velocity fields do not agree because the DeepONet does not strictly obey a no-slip condition. However, aside from the leading edge, the predictions are close to zero. Furthermore, the fields are not directly related to the objective lift-to-drag but indirectly related through the estimate of the change in flow speed over the surface $\frac{dU}{dn}$ obtained by approaches (A) and (B) in Equation[10] and[11]. Therefore, the inaccuracy does not significantly affect the overall objective prediction. This is corroborated by Fig. 9 which shows the sorted lift-to-drag ratio for the entire dataset. The results of both numerical integration approaches (A) and (B) are very accurate to the stored lift-to-drag results from the Nektar++ data generation step. We can also see in the error plot that it is quite uniform, and there are no discernible biases in the geometric parameter space, indicating we have learned the entire space well enough for the final optimized result to be accurate.

4.2 Shape Optimization Results

The objective of shape optimization is to maximize the lift-to-drag ratio over a feasible region of parameters, which are $m$ and $p$ for this case. Equation[12] gives this objective in the form of a minimization problem, as is standard for most optimizers that perform gradient-based or gradient-free optimization. Therefore, the definition of a constrained optimization problem for airfoil is expressed as

$$\begin{align*}
\text{minimize} & \quad f(m, p) \\
\text{subject to} & \quad m_{\text{min}} \leq m \leq m_{\text{max}}, \\
& \quad p_{\text{min}} \leq p \leq p_{\text{max}},
\end{align*}$$

(12)

where $f(m, p)$ represents ratio of lift to drag and $[m_{\text{min}}, m_{\text{max}}]$ and $[p_{\text{min}}, p_{\text{max}}]$ are bounds for feasible search region.

One of the present study’s goals is to optimize the shape for any arbitrary geometry. Therefore, we integrated the DeepONet-based surrogate model with Dakota, which is a multilevel parallel object-oriented framework for design optimization, parameter estimation, uncertainty quantification, and sensitivity analysis[57]. Dakota is freely available and offers a very efficient and scalable implementation. We integrated the DeepONet with Dakota in a modular approach as shown in Algorithm[1] where $D$ is an algorithm chosen from a set of optimizers provided by Dakota and DeepONet-based model $\Phi$ is passed as an argument to $D$. For example, to achieve the solution of Equation[12], we use an efficient global algorithm (EGO), which is a derivative-free approach that uses a Gaussian process model for the optimization of the expected improvement function and is based on the NCSU Direct algorithm[59]. The reason behind choosing this method is to avoid tuning various hyperparameters. To use the algorithm to solve the problem in
Figure 9: Plot of the computed lift-to-drag objective for the entire dataset sorted by the Nektar++ reference values. As seen in both plots, the approximation to the high-fidelity CFD solution is very accurate and consistent throughout the entire parametric domain. Particularly, we note that the testing set performs comparably to the training set, meaning there is little to no generalization error, which is necessary when inferring unseen queried geometries during optimization.

Equation (12), we set a seed, which is to be used for Latin Hypercube Sampling (LHS) to generate the initial set of points for constructing the initial Gaussian process. To gain efficiency, we used batch-sequential parallelization offered by Dakota on an eight-core CPU (2.3 GHz Intel core i9).

Algorithm 1 Integration of DeepONet-based surrogate model with Dakota

```plaintext
Require:
\( m, p, x, y \): maximum camber, the position of maximum camber, spatial coordinates for flow-field prediction

Require: Trained DeepONet: \( G(m, p, x, y) \)

Require: \( D \): \( D \in \) Algorithms in Dakota

Require: \( \Psi(u, v, \rho, p, \xi) \): Function producing the lift \( L \) and drag \( D \)

Require: \( N \): Number of objective function evaluations

Require: \( m_{\min}, m_{\max}, p_{\min}, p_{\max} \): Bounds of feasible region

\( n \leftarrow 0, m_{\text{opt}} \leftarrow m_0, p_{\text{opt}} \leftarrow p_0 \) \hspace{1cm} \text{\( \triangleright \) Initialize}

\( \text{while} \ n \neq N \text{ do} \)

\( m_{\text{opt}}, p_{\text{opt}} \leftarrow D(-f(m_{\text{opt}}, p_{\text{opt}}), m_{\min}, m_{\max}, p_{\min}, p_{\max}, G, \Psi) \) \hspace{1cm} \text{\( \triangleright \) Optimization process for parameters}

\( n \leftarrow n + 1 \)

\( \text{end while} \)
```

The optimization landscapes for approaches (A) and (B) are shown in Fig. 10 obtained by brute force evaluation of the respective objectives. Also plotted are the locations of the dataset in the parameter space \( (p, m) \in [0.2, 0.5] \times [0.0, 0.09] \), displaying the sparse sampling used to obtain accurate optimization results. We also observe that the landscape for this

The optimization process finds the minimizer of function in 15 evaluations, and the optimum value which maximizes $L/D$ is $(m_*, p_*) = (0.2, 0.067)$. To achieve consistency in the optimization process, we ran the EGO algorithm 15 times with different seeds and we observed the same optimal point. Furthermore, we validated the optimization results with a comparison to other approaches in Appendix 5.2. The results obtained from all the approaches are in excellent agreement and reported in detail in Table 6 along with their wall clock times. Finally, the most significant contribution of the paper is shown in Table 4. As we can see, the integration of DeepONet into an airfoil geometry optimization framework has lowered the online cost of new objective evaluations by $32,000+$ times. This makes it entirely possible to have almost real-time optimization results, costing a few minutes instead of days. Furthermore, the trained models can be put on any hardware, such as a standard laptop, and real-time accurate flowfields can be predicted in seconds, meaning the geometry optimization is not hardware dependent at test time. We have demonstrated that integrating DeepONets into a geometry optimization pipeline suffers little in accuracy and provides the tradeoff of obtaining and training on an offline dataset with almost instantaneous optimization results when used online compared to a traditional CFD method.

To validate the parameters of optimized airfoil ($p = 0.2, 0.067$), we compare the streamline plots in Fig. 11 constructed using the flowfields $(u, v)$ obtained from trained DeepONet and Nektar++. In general, the streamline plots show an excellent agreement and therefore validate the workflow of shape optimization presented in this work. DeepONet is able to successfully detect and predict the circulation near the trailing edge of the airfoil. However, a closer look reveals non-physical streamlines originating from the surface of the airfoil. This is due to the error in the velocity fields near the airfoil surface, predicted by the DeepONet. The results can be further improved by giving more importance to the region near the airfoil surface (via proper weighting) during training of the DeepONet.
Figure 11: **Optimized airfoil.** The streamline plot represents the flow past the optimized airfoil with \((p, m) = (0.2, 0.067)\) in \(\Omega_W\). The velocity fields simulated in Nektar++ and predicted by the DeepONets are shown here.

## 5 Conclusions

We have successfully integrated DeepONets as a surrogate model into the shape optimization framework for airfoils. Having summarized prior work in this field, we empirically demonstrate the efficacy of DeepONets in terms of retaining sufficient flowfield accuracy used in evaluating the objective function of lift-to-drag, as well as the significant computational speed up as a replacement for a traditional CFD solver during online geometry optimization. We have provided thorough validation of the results presented as well as extensive experimentation such as two approaches (A) and (B) when approximating the wall shear stress and two forms of DeepONet inputs (NURBS and \(\xi_g\)) to ensure a robust pipeline. Importantly, DeepONets exhibit almost no generalization error over the dataset, so it follows that the resulting optimized geometry \((p = 0.2, m = 0.067)\) is accurate and achieved 32, 253 speed-up compared to the CFD baseline. The framework is general and can address more complex problems with multiple inputs, e.g. different Mach numbers and different angles of attack that can be inputs to either the branch or the trunk networks. Hence, with relatively small modifications, such a framework can handle optimization in the high speed flow regimes that exhibit flow unsteadiness, shocks, non-equilibrium chemistry, and even morphing geometry. Furthermore, the approaches presented are flexible due to the integration of machine learning in the form of function-to-function maps using DeepONet. Therefore, improvements such as the introduction of multi-fidelity training and physics-informed machine learning can be leveraged to reduce the cost of data generation. We also successfully show the application of automatic differentiation, which performs comparably to the traditional approach of finite differences in the wall shear stress calculation. Finally, we hope to utilize transfer learning and uncertainty quantification using the recently developed library NeuralUQ \cite{10.1109/2017} to extrapolate outside of the trained geometric parameter domain to find global optima with confidence.

Appendix

5.1 Nektar++ cross-verification

To ensure a steady-state solution, we selected the flow parameters as $M = 0.5$ and $Re = 500$. Calculating the steady-state solution requires careful consideration. To ensure the steady state solution, for each NACA profile, we recorded the value of conservative variables at six different locations in the wake. We then examined the conservative variables’ time history to ensure the steady state is reached and the solution update has stopped. Fig. 12 shows the location of the history points, where the transient flow could last longer than other spatial locations. As a sample, we plot the time history of variables at point 5 (Fig. 13), which experiences the highest flow fluctuations in time. According to Fig. 13, the solution reached a stationary state when the conservative variables approached constant values.

![Figure 12: History points locations in the wake for NACA airfoils. The conservative variable values are stored in time at these locations to monitor the steady-state solution.](image)

We also validated the simulation setup of NACA airfoils in NekTar++ with the results obtained by an in-house code based on the discontinuous spectral element method of Kopriva [60, 61]. We selected the NACA0020 airfoil for cross-verification. The steady-state solutions of the flow with $M = 0.5$ and $Re = 500$ are computed, and the results are shown in Fig. 14. The flow field primitive variables computed by both solvers agree and show the validity of the NekTar++ simulation setup, including mesh and simulation parameters. According to Fig. 14 the number of elements employed for the NekTar++ simulations is sufficient for an accurate prediction. After validating the flow field, we performed an extra flow simulation around the NACA4402 airfoil. The drag and lift coefficients of this airfoil are reported by Kunz [62] but for an incompressible flow at $Re = 1000$.

We employed the automatic mesh generation setup used for the training set to create the mesh and used the same simulation setup as the training set. We computed the drag and lift coefficients and compared them with the literature. Table 5 compares the drag and lift coefficients computed by Nektar++ with values reported by Kunz [62] for a similar but not exactly the same set up.

5.2 Geometry optimization validation

To validate the main geometry optimization findings in the manuscript using Dakota, we also evaluate the objective function using brute force and SciPy’s dual-annealing method. Brute force is evaluated using a $10 \times 10$ grid on the geometric parameter space $(p, m) \in [0.2, 0.5] \times [0.0, 0.09]$, and therefore requires 100 evaluations of the objective. The dual-annealing method is set to have a maximum amount of 50 evaluations but likely could be set to fewer. As seen in Table 6, all methods discover the same optimal set of parameters and $\frac{L}{T}$, regardless of optimizer or partial approximation given by (A) and (B).
