Atrial fibrillation (AF) is a disorder affecting 20 million people of all ages worldwide, with the incidence increasing with age. It is estimated that 15.9 million people in the USA alone will have the disease by 2050 [1]. AF is the leading cause of stroke, which is the third leading cause of death in the USA. The increased risk of stroke, heart failure, morbidity from anti-coagulation therapy and complications of AF treatment increases the rate of hospitalizations. AF, as a principal diagnosis, comprises over 400,000 hospital admissions and an estimated US$6–7 billion in direct medical expenditure annually in the USA. This in turn makes AF an extreme public health burden – clinically, epidemiologically and economically.

In the last decade, catheter ablation has provided an improvement in morbidity and quality of life, and has significantly reduced long-term healthcare costs by decreasing hospital readmissions and avoiding repeat episodes of care compared with drug therapy [2]. Despite recent progress in techniques, current catheter ablation strategies fall short of expectations [3,4]. In patients with paroxysmal and persistent AF, recurrence rates after 1 year following discontinuation of antiarrhythmic treatment are 70–80% and 50%, respectively. Furthermore, the incidence of significant complications with catheter ablation is approximately 6%. One of these complications, left atrioesophageal fistula, carries with it a very high mortality rate and can be subtle and unrecognized. With occurrences greater than 0.05%, new approaches to prevent left atrioesophageal fistula are needed [5]. In addition, extensive ablation strategies can be proarrhythmic, cause collateral damage to surrounding structures, and decrease atrial transport function and coronary sinus patency. Furthermore, current unreliable methods to ascertain transmural lesion production are being replaced as technology advances.

This inadequate qualification of transmurality could be a contributing factor to recurrence rates. Another consideration should be the use of nontranscending standard lesion sets rather than the use of a tailored approach. A multidisciplinary approach is needed to drive the engine of translation of investigational research into highly patient-personalized treatment plans and procedures. Identification of individual factors that contribute to the development and progression of AF, the success of treatment, and the risk of stroke and death are within reach.
Late gadolinium-enhancement cardiovascular MRI (LGE-MRI) is a well-established tool to image myocardium. The behavior of left atrial (LA) tissue following AF ablation can easily be visualized with the current spatial and temporal resolution of cardiac MRI. Moreover, new computational and mathematical tools now allow us to deal with data dimensionality that is utterly staggering. By developing a new scan sequence at our institution, postablation scarring is quantified based on the distribution of pixel intensities between normal and radio frequency (RF)-induced scarred LA wall tissue. The scan sequence takes advantage of gadolinium’s ability to shorten the T1 relaxation time in its surroundings, thus changing signal intensities.

**LGE-MRI imaging protocols**

In our protocol, scans are acquired approximately 15 min following gadolinium injection (0.1 mmol/kg; MultiHance®, Bracco Diagnostic Inc., NJ, USA). A contrast-enhanced 3D fast low-angle shot angiography sequence and a cine true-fast imaging with steady-state precession sequence are used to define the anatomy of the LA and the pulmonary veins. A 1.5-T Avanto or 3-T Trio clinical scanner (Siemens Medical Solutions, Erlangen, Germany) with a total imaging matrix phased-array receiver coil are used. The sequence for both scanners is a 3D IR prepared fast spoiled gradient recalled sequence that is respiratory triggered and navigated, ECG-gated, gradient-echo and fat suppressed. ECG gating is used to acquire a small subset of phase encoding views during the diastolic phase of the LA cardiac cycle. The time interval between the R-peak of the ECG and the start of data acquisition is defined using the cine images of the LA. A transverse imaging volume with voxel size of 1.25 × 1.25 × 2.5 mm (reconstructed to 0.625 × 0.625 × 1.25 mm) and free breathing using navigator gating is used for both types of scanners.

Flip angles of 20° and 13° are used for the 1.5- and 3-T scanners, respectively. The inversion time (TI) is identified with a scout scan and is between 270 and 310 ms for a 1.5-T scanner and usually from 280 to 330 ms with a 3-T scanner. Other acquisition parameters include the repetition time (TR), which is the time between successive RF pulses, and the echo time (TE), which is the time between RF pulse and measurement; both determine the strength of the signal. TE is chosen such that fat and water are out of phase and the signal intensity of partial volume fat-tissue voxels strength of the signal. TE is chosen such that fat and water are out of phase and the signal intensity of partial volume fat-tissue voxels. TE is chosen such that fat and water are out of phase and the signal intensity of partial volume fat-tissue voxels. TE is chosen such that fat and water are out of phase and the signal intensity of partial volume fat-tissue voxels.

**Clinical applicability of LGE-MRI preablation**

**Stroke risk assessment**

Late gadolinium-enhancement-MRI has provided insights into how to approach planning of strategies for preventative and more individualized care. We know that AF results in LA structural remodeling due to deposition of fibrous tissue that has a characteristic high impedance measurement. We also know that LA structural remodeling increases the risk of thromboembolism in AF patients, making it a potential parameter when assessing a patient’s risk of stroke. Remodeling can now be easily quantified and quantified with the help of LGE-MRI. Furthermore, we have previously shown that LA enhancement using LGE-MRI is more indicative of LA structural remodeling than LA volume.
Review and is a better surrogate marker of remodeling [16]. Therefore, it is plausible that future stroke risk stratification schemes will be more rigorous, based, in part, on individual LA pathophysiological properties. Current schemes have proved to be poor predictors of stroke [17]. More tailored anticoagulation therapy would unquestionably spare low-risk AF patients from the cost, inconvenience and risk of warfarin therapy [17,18]. In addition, more demanding risk assessment will be useful for those with a moderate risk of stroke, a substantial portion of the AF population, because physicians rely heavily on clinical judgment when managing these individuals [17].

We have taken advantage of LGE-MRI to further study the relationship between LA structural remodeling and thromboembolism. In one study, we assigned participants to one of four groups based on their LGE-MRI LA structural remodeling distribution quartiles (Q), expressed as percentage of LA wall enhancement [16]. In doing so, we found that participants at high risk (CHADS₂ ≥2) had a significantly larger amount of LA structural remodeling compared with those with a moderate and low risk. Those with mild remodeling (Q1 <8.5% enhancement) experienced low rates of thromboembolism (2.8%), while over half of those with severe enhancement (Q4 >21.1%) had experienced an ischemic event. We also found that those who had a prior stroke had a significantly higher percentage of remodeling compared with those with no history (24.4 ± 12.4 vs 16.1 ± 9.8%; p < 0.001).

**Structural remodeling staging system**

In addition to releasing collagen-1 and fibronectin-1 inducing factors, evidence exists that atrial myocytes during sustained AF show features resembling myocytes during heart development, which is interpreted as phenotypic changes characteristic of less differentiated cells [19]. It is also suggestive that causality between fibrillation and fibrosis is bidirectional. Various studies have illustrated that extensive structural remodeling correlates to recurrence and worse phenotypic AF. This validates the phenotypic link between fibrosis and disease severity in AF. In addition, those with more pronounced structural remodeling tend to have persistent rather than paroxysmal AF. In a previous study, it was found that the greatest degree of variance for ablation outcome and response to medical therapy was explained by the degree

Review of fibrotic enhancement in the LA wall [16]. The association of enhancement with stroke risk and phenotype of AF offers a means for earlier intervention.

We have developed a specific staging system based on the degree of structural remodeling. The Utah stage system assigns patients to four stages based on the preprocedure LGE-MRI enhancement: Utah I: less than 5%; Utah II: 5–20%; Utah III: 21–35%; and Utah IV: 35% or more (Figure 1) [20]. We found a significant association between the different stages and the clinical outcomes at 1 year (Figure 2). Moreover, this staging system has allowed ablation technologies and strategies to be individualized and better distributed. In those with mild remodeling stages (Utah I and II), we have found that producing lasso-guided antral isolation of all four veins is sufficient to maximize clinical outcomes. On the other hand, on those with more advanced stages of structural remodeling (Utah II and IV), it is imperative further substrate modification is targeted, including posterior wall and septal LA region debulking. Given the extremely poor response rates and higher risk for stroke, one could argue that for patients with severe enhancement (Utah IV >35%) catheter ablation is probably an unnecessary risk to undertake and perhaps a more conservative and palliative therapy for the AF should be pursued.

**LA Doppler & thrombus evaluation**

Transesophageal echocardiogram (TEE) is the accepted standard for evaluation of LA appendage thrombus with high diagnostic accuracy. However, TEE is invasive and, even though the risks are low, can result in complications due to conscious sedation, bleeding and aspiration. Recently, MRI has emerged as a powerful tool to detect thrombus and is significantly less invasive. When imaging for thrombus, MRI has advantages over TEE in the evaluation of soft tissue with multiple imaging sequences that can be employed to help characterize and distinguish between tissue types. Visualization of appendage thrombus has been demonstrated on MRI using bright blood, dark blood and perfusion imaging techniques, with detection enhanced when a combination of these imaging sequences are used [21,22]. In addition, delayed contrast-enhanced T1-weighted (T1w) IR can be used to visualize...
intracardiac thrombi and has been well validated [23,24]. IR imaging utilizes differences in T1 relaxation to create tissue contrast by nulling or enhancing signal. When optimizing the IR sequence and increasing the inversion time, thrombus will appear dark and is differentiated from other tissue (Figure 3). In patients with AF, we have applied T1w IR MRI to detect LAA thrombus and demonstrated its utility in this patient population [22]. Specifically, we have shown LAA thrombus on IR MRI confirmed on TEE with resolution over time after warfarin treatment (Figure 4).

Furthermore, LGE-MRI overcomes the limitations seen with current noninvasive imaging techniques in evaluating the intimate relationship between structure and function of the LA following ablation. In a recent study, segmentation of LA and degree of enhancement was determined using a semi-automated quantification LGE-MRI algorithm and compared with 2D echocardiography. Longitudinal LA strain and strain rate during ventricular systole with velocity vector imaging was found to be inversely related to LA wall fibrosis by LGE-MRI, which is related to the AF burden. These results indicate that echocardiographic assessment of the structure and function of the LA is feasible and helpful in predicting AF outcomes [25].

Expert commentary
Over recent years, catheter ablation of AF has evolve significantly. With the advent of newer technologies, the procedure has become safer and more effective. Unfortunately ablation failures remain a common phenomena. Newer treatment strategies are concentrating on a more individualized treatment plan for patients undergoing AF ablation. Cardiac MRI successfully allows triage of patients preablation, improving our understanding of the individual LA substrate and optimize ablation therapies, achieving better clinical outcomes. The use of cardiac LGE-MRI also provides a comprehensive examination of the patients LA structural remodeling stage, potentially predicting future embolic events and leading to a better allocation of anticoagulation therapy.

Five-year view
Current image integration systems require importation of a MRI image obtained prior to the procedure, thus providing far greater anatomic information and tissue resolution than fluoroscopy, as well as the ability to assess scar formation and structural remodeling. However, this system cannot aid the user during the procedure when RF energy is being applied. Real-time MRI (RT-MRI)-navigated catheter ablation shows promise in term of immediate feedback of lesion formation during RF energy delivery. Furthermore, with RT-MRI, we can monitor the esophagus and pericardial space in real time, reducing complications during ablation procedures. We also gain superior resolution of soft tissue, while sparing both the patient and the operator from the harmful effects of ionizing radiation.
Recent reports of MRI-based catheter tracking and ablation within the atrial chambers using 1.5-T scanners have shown promise, but have also demonstrated their shortcomings. In one study, the authors performed real-time catheter navigation without cardiac imaging during catheter manipulation [26]. In another study, RT-MRI navigation of the catheter was successful, but there wasn’t direct tissue visualization during RF energy delivery and lesion formation [27]. Recently, with real-time 3T MRI (RT-MRI) navigation, our team has been able to guide intracardiac catheter positioning, deliver RF energy and visualize effects on myocardium, assess lesion formation, and visualize heart motion and changes in volume [28]. In addition, we have characterized the early stages of RF lesion formation, and have correlated ablation time to lesion size [28]. Challenges to RT-MRI navigated catheter ablation are still being faced. Automatic detection of catheter tip position with accurate slice alignment is a start to overcoming some of these obstacles.

Key issues
- Atrial fibrillation (AF) is a significant public health issue.
- Catheter ablation has been proven to be an effective rhythm control tool, improving quality of life and reducing costs.
- Despite improved catheter and navigation technologies, AF recurrences after catheter ablation remain problematic.
- Late gadolinium-enhancement cardiovascular (LGE)-MRI allows for specific structural and metabolic imaging of the left atrium prior to ablation.
- Structural remodeling and fibrosis detected by LGE-MRI allows effective triaging of the AF patient, leading to improved clinical outcomes.
- Left atrial fibrosis detected by MRI is a potential independent risk factor for stroke, optimizing allocation of effective anticoagulation strategies in high-risk individuals.
