9.1 Introduction

Direct volume-rendering has proven to be an effective and flexible visualization method for 3D scalar fields. Transfer functions are fundamental to direct volume-rendering because their role is essentially to make the data visible: by assigning optical properties like color and opacity to the voxel data, the volume can be rendered with traditional computer graphics methods. Good transfer functions reveal the important structures in the data without obscuring them with unimportant regions. To date, transfer functions have generally been limited to 1D domains, meaning that the 1D space of scalar data value has been the only variable to which opacity and color are assigned. One aspect of direct volume-rendering that has received little attention is the use of multidimensional transfer functions.

Often, there are features of interest in volume data that are difficult to extract and visualize with 1D transfer functions. Many medical datasets created from CT or MRI scans contain a complex combination of boundaries between multiple materials. This situation is problematic for 1D transfer functions because of the potential for overlap between the data-value intervals spanned by the different boundaries. When one data value is associated with multiple boundaries, a 1D transfer function is unable to render them in isolation. Another benefit of higher dimensional transfer functions is their ability to portray subtle variations in properties of a single boundary, such as thickness. When working with multivariate data, a similar difficulty arises with features that can be identified only by their unique combination of multiple data values. A 1D transfer function is simply not capable of capturing this relationship.

Unfortunately, using multidimensional transfer functions in volume rendering is complicated. Even when the transfer function is only 1D, finding an appropriate transfer function is generally accomplished by trial and error. This is one of the main challenges in making direct volumerendering an effective visualization tool. Adding dimensions to the transfer-function domain only compounds the problem. While this is an ongoing research area, many of the proposed methods for transfer-function generation and manipulation are not easily extended to higherdimensional transfer functions. In addition, fast volume-rendering algorithms that assume the transfer function can be implemented as a linear lookup table (LUT) can be difficult to adapt to multidimensional transfer functions due to the linear interpolation imposed on such LUTs.

This chapter provides a detailed exposition of the multidimensional transfer function concept, a generalization of multidimensional transfer functions for both scalar and multivariate data, as well as a novel technique for the interactive generation of volumetric shadows. To resolve the potential complexities in a user interface for multidimensional transfer functions, we introduce a set of direct manipulation widgets

that make finding and experimenting with transfer functions an intuitive, efficient, and informative process. In order to make this process genuinely interactive, we exploit the fast rendering capabilities of modern graphics hardware, especially 3D texture memory and pixel-texturing operations. Together, the widgets and the hardware form the basis for new interaction modes that can guide users towards transferfunction settings appropriate for their visualization and data-exploration interests.

9.2 Previous Work

9.2.1 Transfer Functions

Even though volume-rendering as a visualization tool is more than ten years old, only recently has research focused on making the space of transfer functions easier to explore. He et al. [12] generated transfer functions with genetic algorithms driven either by user selection of thumbnail renderings or by some objective image-fitness function. The Design Gallery [23] creates an intuitive interface to the entire space of all possible transfer functions based on automated analysis and layout of rendered images. A more data-centric approach is the Contour Spectrum [1], which visually summarizes the space of isosurfaces in terms of metrics like surface area and mean gradient magnitude, thereby guiding the choice of iso-value for isosurfacing, and also providing information useful for transfer-function generation. Another recent paper [18] presents a novel transferfunction interface in which small thumbnail renderings are arranged according to their relationship with the spaces of data values, color, and opacity.

The application of these methods is limited to the generation of 1D transfer functions, even though 2D transfer functions were introduced by Levoy in 1988 [22]. Levoy introduced two styles of transfer functions, both 2D and both using gradient magnitude for the second dimension. One transfer function was intended for the display of interfaces between materials, the other for the display of iso-value contours in more smoothly varying data. The previous work most directly related to our approach for visualizing scalar data facilitates the semiautomatic generation of both 1D and 2D transfer functions [17,29]. Using principles of computer-vision edge detection, the semiautomatic method strives to isolate those portions of the transfer function domain that most reliably correlate with the middle of material-interface boundaries. Other work closely related to our approach for visualizing multivariate data uses a 2D transfer function to visualize data derived from multiple MRI pulse sequences [20].

Scalar volume-rendering research that uses multidimensional transfer functions is relatively scarce. One paper discusses the use of transfer functions similar to Levoy's as part of visualization in the context of wavelet volume representation [27]. More recently, the VolumePro graphics board uses a 12-bit 1D lookup table for the transfer function, but also allows opacity modulation by gradient magnitude, effectively implementing a separable 2D transfer function [28]. Other work involving multidimensional transfer functions uses various types of second derivatives in order to distinguish features in the volume according to their shape and curvature characteristics [15,34].

Designing color maps for displaying non volumetric data is a task similar to finding transfer functions. Previous work has developed strategies and guidelines for color map creation, based on visualization goals, types of data, perceptual considerations, and user studies [3,32,36].

9.2.2 Direct Manipulation Widgets

Direct manipulation widgets are geometric objects rendered with a visualization and are designed to provide the user with a 3D interface [5,14,31,35,38]. For example, a frame widget can be used to select a 2D plane within a volume. Widgets are typically rendered from basic geometric primitives such as spheres, cylinders, and cones. Widget construction is often

guided by a constraint system that binds elements of a widget to one another. Each sub-part of a widget represents some functionality of the widget or a parameter to which the user has access.

9.2.3 Hardware Volume Rendering

Many volume-rendering techniques based on graphics hardware utilize texture memory to store a 3D dataset. The dataset is then sampled, classified, rendered to proxy geometry, and composited. Classification typically occurs in hardware as a 1D table lookup.

2D texture-based techniques slice along the major axes of the data and take advantage of hardware bilinear interpolation within the slice [4]. These methods require three copies of the volume to reside in texture memory, one per axis, and they often suffer from artifacts caused by under-sampling along the slice axis. Trilinear interpolation can be attained using 2D textures with specialized hardware extensions available on some commodity graphics cards [6]. This technique allows intermediate slices along the slice axis to be computed in hardware. These hardware extensions also permit diffuse shaded volumes to be rendered at interactive frame rates.

3D texture-based techniques typically sample view-aligned slices through the volume, leveraging hardware trilinear interpolation [11]. Other elements of proxy geometry, such as spherical shells, may be used with 3D texture methods to eliminate artifacts caused by perspective projection [21]. The pixel texture OpenGL extension has been used with 3D texture techniques to encode both data value and a diffuse illumination parameter that allows shading and classification to occur in the same look-up [25]. Engel et al. showed how to significantly reduce the number of slices needed to adequately sample a scalar volume, while maintaining a high-quality rendering, using a mathematical technique of preintegration and hardware extensions such as dependent textures [10].

Another form of volume-rendering graphics hardware is the Cube-4 architecture [30] and the

subsequent Volume-Pro PCI graphics board [28]. The VolumePro graphics board implements ray casting combined with the shear warp factorization for volume-rendering [19]. It features trilinear interpolation with supersampling, gradient estimation, and shaded volumes, and provides interactive frame rates for scalar volumes with sizes up to 512³.

9.3 Multidimensional Transfer Functions

Transfer-function specification is arguably the most important task in volume visualization. While the transfer function's role is simply to assign optical properties such as opacity and color to the data being visualized, the value of the resulting visualization will be largely dependent on how well these optical properties capture features of interest. Specifying a good transfer function can be a difficult and tedious task for several reasons. First, it is difficult to uniquely identify features of interest in the transfer-function domain. Even though a feature of interest may be easily identifiable in the spatial domain, the range of data values that characterize the feature may be difficult to isolate in the transfer-function domain due to the fact that other, uninteresting regions may contain the same range of data values. Second, transfer functions can have an enormous number of degrees of freedom. Even simple 1D transfer functions using linear ramps require two degrees of freedom per control point. Third, typical user interfaces do not guide the user in setting these control points based on dataset-specific information. Without this type of information, the user must rely on trial and error. This kind of interaction can be especially frustrating since small changes to the transfer function can result in surprisingly large and unintuitive changes to the volumerendering.

Rather than classifying a sample based on a single scalar value, multidimensional transfer functions allow a sample to be classified based on a combination of values. Multiple data

values tend increase the probability that a feature can be uniquely isolated in the transferfunction domain, effectively providing a larger vocabulary for expressing the differences between structures in the dataset. These values are the axes of a multidimensional transfer function. Adding dimensions to the transfer function, however, greatly increases the degrees of freedom necessary for specifying a transfer function and the need for dataset-specific guidance.

In the following sections, we demonstrate the application of multidimensional transfer functions to two distinct classes of data: scalar data and multivariate data. The scalar-data application is focused on locating surface boundaries in a scalar volume. We motivate and describe the axes of the multidimensional transfer function for this type of data. We then describe the use of multidimensional transfer functions for multivariate data. We use two examples, color volumes and meteorological simulations, to demonstrate the effectiveness of such transfer functions.

9.3.1 Scalar Data

For scalar data, the gradient is a first-derivative measure. As a vector, it describes the direction of greatest change. The normalized gradient is often used as the normal for surface-based volume shading. The gradient magnitude is a scalar quantity that describes the local rate of change in the scalar field. For notational convenience, we will use f' to indicate the magnitude of the gradient of f, where f is the scalar function representing the data.

$$f' = \|f\| \tag{9.1}$$

This value is useful as an axis of the transfer function since it discriminates between homogeneous regions (low-gradient magnitudes) and regions of change (high-gradient magnitudes). This effect can be seen in Fig. 9.1. Fig. 9.1a shows a 1D histogram based on data value and identifies the three basic materials in the Chapel Hill CT Head: air (A), soft tissue (B), and bone (C). Fig. 9.1b shows a log-scale joint histogram of data value versus gradient magnitude.

Since materials are relatively homogeneous, their gradient magnitudes are low. They can be seen as the circular regions at the bottom of the histogram. The boundaries between the materials are shown as the arches: air and soft tissue boundary (D), soft tissue and bone boundary (E), and air and bone boundary (F). Each of these materials and boundaries can be isolated using a 2D transfer function based on data value and gradient magnitude. Fig. 9.1c shows a volume-rendering with the corresponding features labeled. The air-bone boundary, (F) in Fig. 9.1, is a good example of a surface that cannot be isolated using a simple 1D transfer function. This type of boundary appears in CT datasets as the sinuses and mastoid cells. Often, the arches that define material boundaries in a 2D transfer function overlap. In some cases this overlap prevents a material from being properly isolated in the transfer function. This effect can be seen in the circled region of the 2D data value-gradient magnitude joint histogram of the human tooth CT in Fig. 9.2a. The background-dentin boundary (F) shares the same ranges of data value and gradient magnitude as portions of the pulpdentin (E) and the background-enamel (H) boundaries. When the background-dentin boundary (F) is emphasized in a 2D transfer function, the boundaries (E) and (H) are erroneously colored in the volume rendering, as seen in Fig. 9.2c. A second derivative measure enables a more precise disambiguation of complex boundary configurations such as this. Some edge-detection algorithms (such as Marr-Hildreth [24]) locate the middle of an edge by detecting a zero crossing in a second derivative measure, such as the Laplacian. We compute a more accurate but computationally expensive measure, the second directional derivative along the gradient direction, which involves the Hessian (H), a matrix of second partial derivatives. We will use f'' to indicate this second derivative.

(a) A ID histogram. The black region represents the number of data value occurrences on a linear scale; the grey is on a log scale. The colored regions (A,B,C) identify basic materials.

(b) A log-scale 2D joint histogram. The lower image shows the location of materials (A,B,C). and material boundaries (D,E,F).

(c) A volume-rendering showing all of the materials and boundaries identified above, except air (A), using a 2D transfer function.

Figure 9.1 Material and boundary identification of the Chapel Hill CT Head with data value alone (a) versus data value and gradient magnitude (f'), seen in (b). The basic materials captured by CT, air (A), soft tissue (B), and bone (C), can be identified using a 1D transfer function as seen in (a). 1D transfer functions, however, cannot capture the complex combinations of material boundaries; air and soft tissue boundary (D), soft tissue and bone boundary (E), and air and bone boundary (F), as seen in (b) and (c).

Figure 9.2 Material and boundary identification of the human tooth CT with data value and gradient magnitude (f'), seen in (a), and data value and second derivative (f''), seen in (b). The background-dentin boundary (F) cannot be adequately captured with data value and gradient magnitude alone. (c) shows the results of a 2D transfer function designed to show only the background-dentin (F) and dentin-enamel boundaries (G). The background-enamel (H) and dentin-pulp (E) boundaries are erroneously colored. Adding the second derivative as a third axis to the transfer function disambiguates the boundaries. (d) shows the results of a 3D transfer function that gives lower opacity to nonzero second-derivative values.

$$f'' = \frac{1}{\|f\|^2} (\nabla f)^{\mathrm{T}} \mathbf{H} f \nabla f$$
(9.2)

More details on these measurements can be found in previous work on semiautomatic transfer function generation [16,17]. Fig. 9.2b shows a joint histogram of data value verses this second directional derivative. Notice that the boundaries (E), (F), and (G) no longer overlap. By reducing the opacity assigned to nonzero second-derivative values, we can render the background-dentin boundary in isolation, as seen in Fig. 9.2d. The relationship between data value, gradient magnitude, and the second directional derivative is made clear in Fig. 9.3. Fig. 9.3a shows the behavior of these values along a line through an idealized boundary between two homogeneous materials (inset). Notice that at the center of the boundary, the gradient magnitude is high and the second derivative is zero. Fig. 9.3b shows the behavior of the gradient magnitude and second derivative as a function of data value. This shows the curves as they appear in a joint histogram or a transfer function.

9.3.2 Multivariate data

Multivariate data contains, at each sample point, multiple scalar values that represent different simulated or measured quantities. Multivariate data can come from numerical simulations that calculate a list of quantities at each time step, or from medical scanning modalities such as MRI, which can measure a variety of tissue characteristics, or from a combination of different scanning modalities, such as MRI, CT, and PET. Multidimensional transfer functions are an obvious choice for volume visualization of multivariate data, since we can assign different data values to the different axes of the transfer function. It is often the case that a feature of interest in these datasets cannot be properly classified using any single variable by itself. In addition, we can compute a kind of first derivative in the multivariate data in order to create more information about local structure. As with scalar data, the use of a first derivative measure as one axis of the multidimensional transfer function can increase the specificity with which we can isolate and visualize different features in the data.

Figure 9.3 The behavior of primary data value (f), gradient magnitude (f'), and the second directional derivative (f'') as a function of position (a) and as a function of data value (b).

One example of data that benefits from multidimensional transfer functions is volumetric color data. A number of volumetric color datasets are available, such as the Visible Human Project's RGB data. The process of acquiring color data by cryosection is becoming common for the investigation of anatomy and histology. In these datasets, the differences in materials are expressed by their unique spectral signatures. A multidimensional transfer function is a natural choice for visualizing this type of data. Opacity can be assigned to different positions in the 3D RGB color space.

Fig. 9.4a shows a joint histogram of the RGB color data for the Visible Male; regions of this space that correspond to different tissues are identified. Regions (A) and (B) correspond to the fatty tissues of the brain, white and gray matter, as seen in Fig. 9.4b. In this visualization, the transition between white and grey matter is intentionally left out to better emphasize these materials and to demonstrate the expressivity of the multidimensional transfer function Fig. 9.4c shows a visualization of the color values that represent the muscle structure and connective tissues (C) of the head and neck with the skin surface (D), given a small amount of opacity for

context. In both of these figures, a slice of the original data is mapped to the surface of the clipping plane for reference.

The kind of first derivative that we compute in multivariate data is based on previous work in color image segmentation [8,33,7]. While the gradient magnitude in scalar data represents the magnitude of local change at a point, an analogous first-derivative measure in multivariate data captures the total amount of local change, across all the data components. This derivative has proven useful in color image segmentation because it allows a generalization of gradient-based edge detection. In our system, we use this first-derivative measure as one axis in the multidimensional transfer function in order to isolate and visualize different regions of a multivariate volume according to the amount of local change, analogous to our use of gradient magnitude for scalar data.

If we represent the dataset as a multivariate function $\mathbf{f}(x,y,z)$: $\mathbb{R}^3 \to \mathbb{R}^m$, so that

$$\mathbf{f}(x, y, z) = (f_1(x, y, z), f_2(x, y, z), \dots, f_m(x, y, z))$$

then the derivative Df is a matrix of first partial derivatives:

(a) Histograms of the Visible Male RGB dataset

(b) The white (A) and gray (B) matter of the brain

(c) The muscle and connective tissues (C) of the head and neck, showing skin (D) for reference

Figure 9.4 The Visible Male RGB (color) data. The opacity is set using a 3D transfer function, and color is taken directly from the data. The histogram (a) is visualized as projections on the primary planes of the RGB color space.

$$\mathbf{Df} = \begin{bmatrix} \frac{\partial f_1}{\partial x} & \frac{\partial f_1}{\partial y} & \frac{\partial f_1}{\partial z} \\ \frac{\partial f_2}{\partial x} & \frac{\partial f_2}{\partial y} & \frac{\partial f_2}{\partial z} \\ \vdots \\ \frac{\partial f_m}{\partial x} & \frac{\partial f_m}{\partial y} & \frac{\partial f_m}{\partial z} \end{bmatrix}$$

By multiplying **Df** with its transpose, we can form a 3×3 tensor **G** that captures the directional dependence of total change:

$$\mathbf{G} = (\mathbf{D}\mathbf{f})^{\mathrm{T}}\mathbf{D}\mathbf{f} \tag{9.3}$$

In the context of color edge detection [8,33,7], this matrix (specifically, its 2D analog) is used as the basis of a quadratic function of direction n, which Cumani [7] terms the *squared local contrast* in direction n:

$$S(\mathbf{n}) = \mathbf{n}^{\mathrm{T}} \mathbf{G} \mathbf{n}$$

S(n) can be analyzed by finding the principal eigenvector (and associated eigenvalue) of **G** to determine the direction **n** of greatest local contrast, or fastest change, and the magnitude of that change. Our experience, however, has been that in the context of multidimensional transfer functions, it is sufficient (and perhaps preferable) to simply take the L2 norm of **G**, ||**G**||,

which is the square root of the sum of the squares root of the sum of the squares of the individual matrix components. As the L2 norm is invariant with respect to rotation, this is the same as the L2 norm of the three eigenvalues of **G**, motivating our use of $||\mathbf{G}||$ as a directionally independent (and rotationally invariant) measure of local change. Other work on volume-rendering of color data has used a non-rotationally invariant measure of G [9]. Since it is sometimes the case that the dynamic range of the individual channels (f_i) differ, we normalize the ranges of each channel's data value to be between zero and one. This allows each channel to have an equal contribution in the derivative calculation.

9.4 Interaction and Tools

While adding dimensions to the transfer function enhances our ability to isolate features of interest in a dataset, it tends to make the already unintuitive space of the transfer function even more difficult to navigate. This difficulty can be considered in terms of a conceptual gap between the spatial and transfer-function domains. The spatial domain is the familiar 3D space for geometry and the volume data being rendered. The transfer-function domain, however, is more abstract. Its dimensions are not spatial (i.e. the ranges of data values), and the quantities at each location are not scalar (i.e. opacity and three colors). It can be very difficult to determine the regions of the transfer function that correspond to features of interest, especially when a region is very small. Thus, to close this conceptual gap, we developed new interaction techniques, which permit interaction in both domains simultaneously, and a suite of direct manipulation widgets that provide the tools for such interactions. Fig. 9.5 shows the various direct manipulation widgets as they appear in the system.

In a typical session with our system, the user creates a transfer function using a natural process of exploration, specification, and refinement. Initially, the user is presented with a volume-rendering using a predetermined transfer function that is likely to bring out some features of interest. This can originate with an

Figure 9.5 The direct-manipulation widgets.

automated transfer function generation tool [16], or it could be the default transfer function described later in Section 9.6. The user would then begin exploring the dataset.

Exploration is the process by which a user familiarizes him or herself with the dataset. A clipping plane can be moved through the volume to reveal internal structures. A slice of the original data can be mapped to the clipping plane, permitting a close inspection of the entire range of data values. Sample positions are probed in the spatial domain, and their values, along with values in a neighborhood around that point, are visualized in the transferfunction domain. This feedback allows the user to identify the regions of the transfer function that correspond to potential features of interest, made visible by the default transfer function or the sliced data. Once these regions have been identified, the user can then begin specifying a custom transfer function.

During the specification stage, the user creates a rough draft of the desired transfer function. While this can be accomplished by manually adding regions to the transfer function, a simpler method adds opacity to the regions in the transfer function at and around locations queried in the spatial domain. That is, the system can track, with a small region of opacity in the transfer-function domain, the data values at the user-selected locations, while continually updating the volume-rendering. This visualizes, in the spatial domain, all other voxels with similar transfer-function values. If the user decides that an important feature is captured by the current transfer function, he or she can add that region into the transfer function and continue querying and investigating the volume.

Once these regions have been identified, the user can refine them by manipulating control points in the transfer-function domain to better visualize features of interest. An important feature of our system is the ability to manipulate portions of the transfer function as discrete entities. This permits the modification of regions corresponding to a particular feature without affecting other classified regions.

Finally, this is an iterative process. A user continues the exploration, specification, and refinement steps until they are satisfied that all features of interest are made visible. In the remainder of this section, we will introduce the interaction modalities used in the exploration and specification stages and briefly describe the individual direct manipulation widgets.

9.4.1 Probing and Dual-Domain Interaction

The concept of probing is simple: The user points at a location in the spatial domain and visualizes the values at that point in the transferfunction domain. We have found this feedback to be essential for making the connection between features seen in the spatial domain and the ranges of values that identify them in the transfer-function domain. Creating the best transfer function for visualizing a feature of interest is only possible with an understanding of the behavior of data values at and around that feature. This is especially true for multidimensional transfer functions where a feature is described by a complex combination of data values. The value of this dataset-specific guidance can be further enhanced by automatically setting the transfer function based on these queried values.

In a traditional volume-rendering system, setting the transfer function involves moving the control points (in a sequence of linear ramps defining color and opacity), and then observing the resulting rendered image. That is, interaction in the transfer-function domain is guided by careful observation of changes in the spatial domain. We prefer a reversal of this process, in which the transfer function is set by direct interaction in the spatial domain, with observation of the transfer-function domain. Furthermore, by allowing interaction to happen in both domains simultaneously. We significantly lessen the conceptual gap between them, effectively simplifying the complicated task of specifying a multidimensional transfer function to pointing at a feature of interest. We use the term "dualdomain interaction" to describe this approach to transfer-function exploration and generation.

The top of Fig. 9.6 illustrates the specific steps of dual-domain interaction. When a position inside the volume is gueried by the user with the data probe widget (a), the values associated with that position (multivariate values, or the data value, first and second derivative) are graphically represented in the transfer function widget (b). Then, a small region of high opacity (c) is temporarily added to the transfer function at the data values determined by the probe location. The user has now set a multidimensional transfer function simply by positioning a data probe within the volume. The resulting rendering (d) depicts (in the spatial domain) all the other locations in the volume that share values (in the transfer-function domain) with those at the data probe tip. If the features rendered are of interest, the user can copy the temporary transfer function to the permanent one (e), by, for instance, tapping the keyboard space bar with the free hand. As features of interest are discovered. they can be added to the transfer function quickly and easily with this type of two-handed interaction. Alternately, the probe feedback can be used to manually set other types of classification widgets (f), which are described later. The outcome of dual-domain interaction is an effective multidimensional transfer function built up over the course of data exploration. The widget components that participated in this process can be seen in the bottom of Fig. 9.6, which shows how dual-domain interaction can help volume-render the CT tooth dataset. The remainder of this section describes the individual widgets and provides additional details about dual-domain interaction.

9.4.2 Data Probe Widget

The data probe widget is responsible for reporting its tip's position in volume space and its slider sub-widget's value. Its pencil-like shape is designed to give the user the ability to point at a feature in the volume being rendered. The other end of the widget orients the widget about its tip.

Figure 9.6 Dual-Domain Interaction

When the volume-rendering's position or orientation is modified the data probe widget's tip tracks its point in volume space. A natural extension is to link the data probe widget to a haptic device, such as the SensAble PHANTOM, which can provide a direct 3D location and orientation [26].

9.4.3 Clipping Plane Widget

The clipping plane is responsible for reporting its orientation and position to the volume renderer, which handles the actual clipping when it draws the volume. In addition to clipping, the volume widget will also map a slice of the data to the arbitrary plane defined by the clip widget, and blend it with the volume by a constant opacity value determined by the clip widget's slider. It is also responsible for reporting the spatial position of a mouse click on its clipping surface. This provides an additional means of querying positions within the volume, distinct from the 3D data probe. The balls at the corners of the clipping plane widget are used to modify its orientation, and the bars on the edges are used to modify its position.

9.4.4 Transfer-Function Widget

The main role of the transfer-function widget is to present a graphical representation of the transfer-function domain, in which feedback from querying the volume (with the data probe or clipping plane) is displayed, and in which the transfer function itself can be set and altered. The balls at the corners of the transfer-function

widget are used to resize it, as with a desktop window, and the bars on the edges are used to translate its position. The inner plane of the frame is a polygon texture-mapped with the lookup table containing the transfer function. A joint histogram of data, seen with the images in Section 9.3, can also be blended with the transfer function to provide valuable information about the behavior and relationship of data values in the transfer-function domain.

The data values at the position queried in the volume (via either the data probe or the clipping plane widget) are represented with a small ball in the transfer-function widget. In addition to the precise location queried, the eight data sample points at the corners of the voxel containing the query location are also represented by balls in the transfer-function domain, and are connected together with edges that reflect the connectivity of the voxel corners in the spatial domain. By "reprojecting" a voxel from the spatial domain to a simple graphical representation in the transfer-function domain, the user can learn how the transfer-function variables (data values at each sample point) are changing near the probe location. The values for the third, or unseen, axis are indicated by coloring son the balls. For instance, with scalar data, second-derivative values that are negative, zero, and positive are represented by blue, white, and yellow balls, respectively. When the projected points form an arc, with the color varying through these assigned colors, the probe is at a boundary in the volume as seen in Fig. 9.5. When the reprojected data points are clustered together, the probe is in a homogeneous region. As the user gains experience with this representation, he or she can learn to "read" the reprojected voxel as an indicator of the volume characteristics at the probe location.

9.4.5 Classification Widgets

In addition to the process of dual-domain interaction described above, transfer functions can also be created in a more manual fashion by adding one or more classification widgets to the main transfer-function window. Classification widgets are designed to identify regions of the transfer function as discrete entities. Each widget type has control points that modify its position or size. Optical properties, such as opacity and color, are modified by selecting the widget's inner surface. The opacity and color contributions from each classification widget are blended together to form the transfer function. We have developed two types of classification widget: triangular and rectangular.

The triangular classification widget, shown in Figs. 9.5, 9.6, and 9.8, is based on Levoy's "isovalue contour surface" opacity function [22]. The widget is an inverted triangle with a base point attached to the horizontal data value axis. The triangle's size and position are adjusted with control points. There are an upper and lower threshold for the gradient magnitude, as well as a shear. Color is constant across the widget; opacity is maximal along the center of the widget, and it linearly ramps down to zero at the left and right edges.

The triangular classification widgets are particularly effective for visualizing *surfaces* in scalar data. More general transfer functions, for visualizing data that may not have clear boundaries, can be created with the rectangular classification widget. The rectangular region spanned by the widget defines the data values that receive opacity and color. Like the triangular widget, color is constant, but the opacity is more flexible. It can be constant, or fall off in various ways: quadratically as an ellipsoid with axes corresponding to the rectangle's aspect ratio, or linearly as a ramp, tent, or pyramid.

As noted in the description of the transferfunction widget, even when a transfer function has more than two dimensions, only two dimensions are shown at any one time. For 3D transfer functions, classification widgets are shown as their projections onto the visible axes. In this case, a rectangular classification widget becomes a box in the 3D domain of the transfer function. Its appearance to the user, however, as 2D projections, is identical to the rectangular widget. When the third axis of the transfer function plays a more simplified role, interactions along this axis are tied to sliders seen along the top bar of the transfer function. For instance, since our research on scalar data has focussed on visualizing boundaries between material regions, we have consistently used the second derivative to emphasize the regions where the second-derivative magnitude is small or zero. Specifically, maximal opacity is always given to zero second derivatives, and decreases linearly towards the second-derivative extrema values. How much the opacity changes as a function of second-derivative magnitude is controlled with a single slider, which we call the "boundary emphasis slider." With the slider in its left-most position, zero opacity is given to extremal second derivatives; in the right-most position, opacity is constant with respect to the second derivative. We have employed similar techniques for manipulating other types of thirdaxis values using multiple sliders.

While the classification widgets are usually set by hand in the transfer-function domain, based on feedback from probing and reprojected voxels, their placement can also be somewhat automated. This further reduces the difficulty of creating an effective higher-dimensional transfer function. The classification widget's location and size in the transfer-function domain can be tied to the distribution of the reprojected voxels determined by the data probe's location. For instance, the rectangular classification widget can be centered at the transfer-function values interpolated at the data probe's tip, with the size of the rectangle controlled by the data probe's slider. The triangular classification widget can be located horizontally at the data value queried by the probe, with the width and height determined by the horizontal and vertical variance in the reprojected voxel locations. This technique produced the changes in the transfer function for the sequence of renderings in Fig. 9.6

9.4.6 Shading Widget

The shading widget is a collection of spheres that can be rendered in the scene to indicate

and control the light direction and color. Fixing a few lights in view space is generally effective for renderings; therefore, changing the lighting is an infrequent operation.

9.4.7 Color-Picker Widget

The color picker is an embedded widget that is based on the hue-lightness-saturation (HLS) color space. Interacting with this widget can be thought of as manipulating a sphere with hues mapped around the equator, gradually becoming black at the top and white at the bottom. To select a hue, the user moves the mouse horizontally, rotating the ball around its vertical axis. Vertical mouse motion tips the sphere toward or away from the user, shifting the color towards white or black. Saturation and opacity are selected independently using different mouse buttons with vertical motion. While this color picker can be thought of as manipulating an HLS sphere, no geometry for this is rendered. Rather, the triangular and rectangular classification widgets embed the color picker in the polygonal region, which contributes opacity and color to the transfer-function domain. The user specifies a color simply by clicking on that object, then moving the mouse horizontally and vertically until the desired hue and lightness are visible. In most cases, the desired color can be selected with a single mouse-click and gesture.

9.5 Rendering and Hardware

While this chapter is conceptually focused on the matter of setting and applying higherdimensional transfer functions, the quality of interaction and exploration described would not be possible without the use of modern graphics hardware. Our implementation relies heavily on an OpenGL extension known as *dependent texture reads*. This extension can be used for both classification and shading. In this section, we describe our modifications to the classification portion of the traditional 3D texture-based volume-rendering pipeline. We also describe methods for adding interactive volumetric shading and shadows to the pipeline.

Our system supports volumes that are stored as 3D textures with one, two, or four values per texel. This is is due to memory-alignment restrictions of graphics hardware. Volumes with three values per sample utilize a four-value texture, where the fourth value is simply ignored. Volumes with more than four values per sample could be constructed using multiple textures.

9.5.1 Dependent Texture Reads

Dependent texture reads are hardware extensions that are similar but more efficient implementations of a previous extension known as pixel texture [10,13,25,37]. Dependent texture reads and pixel texture are names for operations that use color fragments to generate texture coordinates, and replace those color fragments with the corresponding entries from a texture. This operation essentially amounts to an arbitrary function evaluation with up to three variables via a lookup table. If we were to perform this operation on an RGB fragment, each channel value would be scaled between zero and one. and these new values would then be used as texture coordinates of a 3D texture. The color values produced by the 3D texture lookup replace the original RGB values. The nearestneighbor or linear-interpolation methods can be used to generate the replacement values. The ability to scale and interpolate color channel values is a convenient feature of the hardware. It allows the number of elements along a dimension of the texture containing the new color values to differ from the dynamic range of the component that generated the texture coordinate. Without this flexibility, the size of a 3D dependent texture would be prohibitively large.

9.5.2 Classification

Dependent-texture reads are used for the transfer-function evaluation. Data values stored in the color components of a 3D texture are interpolated across some proxy geometry, a

plane, for instance. These values are then converted to texture coordinates and used to acquire the color and alpha values in the transfer-function texture per-pixel in screen space. For eight-bit data, an ideal transfer-function texture would have 256 color and alpha values along each axis. For 3D transfer functions, however, the transfer-function texture would then be $256^3 \times 4$ bytes. Besides the enormous memory requirements of such a texture, the size also affects how fast the classification widgets can be rasterized, thus affecting the interactivity of transfer-function updates. We therefore limit the number of elements along an axis of a 3D transfer function based on its importance. For instance, with scalar data, the primary data value is the most important, the gradient magnitude is secondary, and the second derivative serves an even more tertiary role. For this type of multidimensional transfer function, we commonly use a 3D transfer-function texture with dimensions $256 \times 128 \times 8$ for data value, gradient magnitude, and second derivative, respectively. 3D transfer functions can also be composed separably as a 2D and a 1D transfer function. This means that the total size of the transfer function is $256^2 + 256$. The tradeoff, however, is in expressivity. We can no longer specify a transfer function based on the unique combination of all three data values. Separable transfer functions are still quite powerful. Applying the second derivative as a separable 1D portion of the transfer function is quite effective for visualizing boundaries between materials. With the separable 3D transfer function for scalar volumes, there is only one boundary-emphasis slider that affects all classification widgets, as opposed to the general case where each classification widget has its own boundary-emphasis slider. We have employed a similar approach for multivariate data visualization. The meteorological example used a separable 3D transfer function. Temperature and humidity were classified using a 2D transfer function and the multiderivative of these values was classified using a 1D transfer function. Since our specific goal was to show only regions with high values of ||G||, we needed only two sliders to specify the beginning and ending points of a linear ramp along this axis of the transfer function.

9.5.3 Surface Shading

Shading is a fundamental component of volume-rendering because it is a natural and efficient way to express information about the shape of structures in the volume. However, much previous work with texture-memory-based-volume-rendering lacks shading. Many modern graphics hardware platforms support multitexture and a number of user-defined operations for blending these textures per-pixel. These operations, which we will refer to as fragment shading, can be leveraged to compute a surface-shading model.

The technique originally proposed by Rezk-Salama et al. [6] is an efficient way to compute the Blinn-Phong shading model on a per-pixel basis for volumes. This approach, however, can suffer from artifacts caused by denormalization during interpolation. While future generations of graphics hardware should support the square root operation needed to renormalize on a perpixel basis, we can utilize cube map dependent texture reads to evaluate the shading model. This type of dependent texture read allows an RGB color component to be treated as a vector and used as the texture coordinates for a cube map. Conceptually, a cube map can be thought of as a collection of six textures that make up the faces of a cube centered about the origin. Texels are accessed with a 3D texture coordinate (s,t,r) representing a direction vector. The accessed texel is the point corresponding to the intersection of a line through the origin in the direction of (s,t,r) and a cube face. The color values at this position represent incoming diffuse radiance if the vector (s,t,r) is a surface normal or specular radiance if (s,t,r) is a reflection vector. The advantages of using a cube map dependent texture read is that the vector (s,t,r)does not need to be normalized, and the cube map can encode an arbitrary number of lights or a full environment map. This approach, however, comes at the cost of reduced performance. A per-pixel cube map evaluation can be as much as three times slower than evaluating the dot products for a limited number of light sources in the fragment shader stage.

Surface-based shading methods are well suited for visualizing the boundaries between materials. However, since the surface normal is approximated by the normalized gradient of a scalar field, these methods are not robust for shading homogeneous regions, where the gradient magnitude is very low or zero and its measurement is sensitive to noise. Gradient-based surface shading is also unsuitable for shading volume-renderings of multivariate fields. While we can assign the direction of greatest change for a point in a multivariate field to the eigenvector (e_1) corresponding to the largest eigenvalue (λ_1) of the tensor **G** from Equation 9.3, e_1 is a valid representation of only orientation, not the absolute direction. This means that the sign of e_1 can flip in neighboring regions even though their orientations may not differ. Therefore, the vector e_1 does not interpolate, making it a poor choice of surface normal. Furthermore, this orientation may not even correspond to the surface normal of a classified region in a multivariate field.

9.5.4 Shadows

Shadows provide important visual queues relating to the depth and placement of objects in a scene. Since the computation of shadows does not depend on a surface normal, they provide a robust method for shading homogeneous regions and multivariate volumes. Adding shadows to the volume lighting model means that light gets attenuated through the volume before being reflected back to the eye.

Our approach differs from previous hardware shadow work [2] in two ways. First, rather than creating a volumetric shadow map, we utilize an off-screen render buffer to accumulate the amount of light attenuated from the light's point of view. Second, we modify the slice axis

to be the direction halfway between the view and light directions. This allows the same slice to be rendered from both the eye and the light points of view. Consider the situation for computing shadows when the view and light directions are the same, as seen in Fig. 9.7a. Since the slices for both the eye and the light have a oneto-one correspondence, it is not necessary to precompute a volumetric shadow map. The amount of light arriving at a particular slice is equal to one minus the accumulated opacity of the slices rendered before it. Naturally, if the projection matrices for the eve and the light differ, we need to maintain a separate buffer for the attenuation from the light's point of view. When the eye and light directions differ, the volume would be sliced along each direction independently. The worst-case scenario happens when the view and light directions are perpendicular, as seen in Fig. 9.7b. In the case, it would seem necessary to save a full volumetric shadow map that can be resliced with the data volume

from the eye's point of view providing shadows. This approach, however, suffers from an artifact referred to as attenuation leakage. The visual consequences of this are blurry shadows and surfaces that appear much darker than they should due to the image-space high frequencies introduced by the transfer function. The attenuation at a given sample point is blurred when light intensity is stored at a coarse resolution and interpolated during the observer rendering phase. This use of a 2D shadow buffer is similar to the method described in Chapter 8 except we address slice-based volume-rendering while they address splatting.

Rather than slice along the vector defined by the view direction or the light direction, we modify the slice axis to allow the same slice to be rendered from both points of view. When the dot product of the light and view directions is positive, we slice along the vector halfway between the light and view directions, seen in Fig. 9.7c. In this case, the volume is rendered in

Figure 9.7 Modified slice axis for light transport.

front-to-back order with respect to the observer. When the dot product is negative, we slice along the vector halfway between the light and the inverted-view directions, seen in Fig. 9.7d. In this case, the volume is rendered in back-to-front order with respect to the observer. In both cases the volume is rendered in front-to-back order with respect to the light. Care must be taken to insure that the slice spacing along the view and light directions are maintained when the light or eye positions change. If the desired slice spacing along the view direction is d_v and the angle between v and l is θ , then the slice spacing along the slice spacing along the slice spacing along the slice direction is

$$d_s = \cos\left(\frac{\theta}{2}\right) d_v \tag{9.4}$$

This is a multi-pass approach. Each slice is first rendered from the observer's point of view using the results of the previous pass from the light's point of view, which modulates the brightness of samples in the current slice. The same slice is then rendered from light's point of view to calculate the intensity of the light arriving at the next layer.

Since we must keep track of the amount of light attenuated at each slice, we utilize an offscreen render buffer, known as a pixel buffer. This buffer is initialized to 1 - light intensity. It can also be initialized using an arbitrary image to create effects such as spotlights. The projection matrix for the light's point of view need not be orthographic; a perspective projection matrix can be used for point light sources. However, the entire volume must fit in the light's view frustum. Light is attenuated by simply accumulating the opacity for each sample using the over operator. The results are then copied to a texture that is multiplied with the next slice from the eye's point of view before it is blended into the frame buffer. While this copy-to-texture operation has been highly optimized on the current generation of graphics hardware, we have achieved a dramatic increase in performance using a hardware extension known as render to texture. This extension allows us to directly bind a pixel buffer as a texture, avoiding the unnecessary copy operation.

This approach has a number of advantages over previous volume shadow methods. First, attenuation leakage is no longer a concern because the computation of the light transport (slicing density) is decoupled from the resolution of the data volume. Computing light attenuation in image space allows us to match the sampling frequency of the light transport with that of the final volume-rendering. Second, this approach makes far more efficient use of memory resources than those that require a volumetric shadow map. Only a single additional 2D buffer is required, as opposed to a potentially large 3D volume. One disadvantage of this approach is that, due to the image-space sampling, artifacts may appear at shadow boundaries when the opacity makes a sharp jump from low to high. This can be overcome by using a higher resolution for the light buffer than for the frame buffer. We have found that 30%-50% additional resolution is adequate.

As noted at the end of the previous section, surface-based shading models are inappropriate for homogeneous regions in a volume. However, it is often useful to have both surface-shaded and shadowed renderings regardless of whether or not homogeneous regions are being visualized. To insure that homogeneous regions are not surface shaded, we simply interpolate between surface-shaded and unshaded using the gradient magnitude. Naturally, regardless of whether or not a particular sample is surface shaded, it is still modulated by the light attenuation providing shadows. In practice we have found that interpolating based on $1 - (1 - \|\nabla f\|)^2$ produces better results, since mid-range gradient magnitudes can still be interpreted as surface features. Fig. 9.8 shows a rendering that combines surface shading and shadows in such a way. Fig. 9.1 shows a volume-rendering using shadows with the light buffer initialized to simulate a spotlight. Fig. 9.2 shows volume-rendering using only surface-based shading. Fig. 9.4 uses only shadows for illumination.

9.6 Discussion

Using multidimensional transfer functions heightens the importance of densely sampling the voxel data in rendering. With each new axis in the transfer function, there is another dimension along which neighboring voxels can differ. It becomes increasingly likely that the data sample points at the corners of a voxel straddle an important region of the transfer function (such as a region of high opacity) instead of falling within it. Thus, in order for the boundaries to be rendered smoothly, the distance between view-aligned sampling planes through the volume must be very small. Most of the figures in this paper were generated with rates of about 3 to 6 samples per voxel. At this sample rate, frame updates can take nearly a second for a moderately sized ($256 \times$ 256×128) shaded and shadowed volume. For this reason, we lower the sample rate during interaction, and rerender at the higher sample rate once an action is completed. During interaction, the volume-rendered surface will appear coarser, but the surface size and location are usually readily apparent. Thus, even with lower volume-sampling rates during interaction, the rendered images are effective feedback for guiding the user in transfer-function exploration.

While the triangular classification widget is based on Levov's iso-contour classification function, we have found it necessary to have additional degrees of freedom, such as a shear. Shearing the triangle classification along the data value axis, so that higher values are emphasized at higher gradients, allows us to follow the center of some boundaries more accurately. This is a subtle but basic characteristic of boundaries between a material with a narrow distribution of data values and another material with a wide value distribution. This pattern can be observed in in the boundary between soft tissue (Fig. 9.9 narrow value distribution) and bone (wide value distribution) of the Visible Male CT, seen in Fig. 9.9. Thresholding the minimum gradient magnitude allows better feature discrimination.

While multidimensional transfer functions are quite effective for visualizing material boundaries, we have also found them to be useful for visualizing the materials themselves. For instance, if we attempt to visualize the dentin of the Human Tooth CT using a 1D transfer function, we erroneously color the background–enamel boundary, seen in Fig. 9.10a. The reason for this can be seen in Fig. 9.2a, where the range of data values that define the background–enamel boundary overlap with the dentin's data values. We can

Soft Tissue Bone

Figure 9.9 The soft tissue–bone boundary of the Visible Male CT. It is necessary to shear the triangular classification widget to follow the center of this boundary.

(a) A 1D transfer function

(b) A 2D transfer function

Figure 9.10 The dentin of the Human Tooth CT (a) shows that a 1D transfer function, simulated by assigning opacity to data values regardless of gradient magnitude, will erroneously color the background–enamel boundary. A 2D transfer function, shown in (b), can avoid assigning opacity to the range of gradient magnitudes that define this boundary.

easily correct this erroneous coloring with a 2D transfer function that gives opacity only to lower-gradient magnitudes. This can be seen in Fig. 9.10b.

A further benefit of dual-domain interaction is the ability to create feature-specific multidimensional transfer functions, which would be extremely difficult to produce by manual place-

ment of classification widgets. If a feature can be visualized in isolation with only a very small and accurately placed classification widget, the best way to place the widget is via dual-domain interaction.

Dual-domain interaction has utility beyond setting multidimensional transfer functions. Dual-domain interaction also helps answer other questions about the limits of direct volumerendering for displaying specific features in the data. For example, the feedback in the transferfunction domain can show the user whether a certain feature of interest detected during spatial domain interaction is well-localized in the transfer function domain. If reprojected voxels from different positions, in the same feature, map to widely divergent locations in the transfer-function domain, then the feature is not well localized, and it may be hard to create a transfer function the clearly visualizes it. Similarly, if probing inside two distinct features indicates that the reprojected voxels from both features map to the same location in the transfer-function domain, then it may be difficult to selectively visualize one or the other feature.

Acknowledgments

The authors would like to thank Al McPherson from the ACL at LANL for fruitful and provocative conversations about volumetric shadows. This research was funded by grants from the Department of Energy (VIEWS 0F00584), the National Science Foundation (ASC 8920219, MRI 9977218, ACR 9978099), and the National Institutes of Health National Center for Research Resources (1P41RR12553-2). We would also like to thank NVIDIA, ATI and sgi for their making their latest generations of hardware available.
